1. Introduction

Radioisotopes are needed for the detection of functional disorders of organs in medical physics and diagnosis and in treatment of many diseases. Nuclear reactions are used for the production of radioisotopes. Possibility to estimate the probability of the realization of a nuclear reaction will very beneficial, from the financial point of view. It will also eliminate the risk of physical exposure to radiation. It is important to be able to estimate the effective energy range of a reaction. Reaction cross section gives information about the probability of the realization of a nuclear reaction.

Co-57 is the most used radionuclide in the scintigraphic imaging applied in diagnostics. It has a half-life of 6 hours. Produced in radioisotope generators, it does not emit particle radiation. It emits only gamma rays with single energy of 140 keV. Such physical properties are ideal for the gamma imaging technique. The properties of $^{99m}$Tc ensure good quality of scintigraphic images and a low radiation dose to which the patient is exposed [1].

In-111 is used for monitoring of organs like liver and kidneys, in the tumor imaging and in the treatment of leukemia. It has a half-life of 2.81 days. It emits gamma photons with energies of 172 keV (91%) and 247 keV (94%) [2].

Co-57 is used for monitoring of kidneys, bladder, liver and bone marrow. It is used for radioisotope dose calibrators in nuclear medicine and as a gamma-source in the measurement systems and gamma cameras. It is used also in the calibration of quality control detectors [3]. It emits photon energies of 122 keV (86%) and 136 keV (10%) [2]. It has a half-life of 270 days.

Ideal radioisotope should emit in the energy range of 100–200 keV and have a suitable half-life. It should be easily obtainable and should have an appropriate price. This theoretical study of production of radioisotopes, used in kidney imaging, is of informative nature.

Different studies have been using TALYS code for calculation of nuclear reaction cross sections. Cross sections of the (n,f) reaction for $^{235}$U have been calculated in [3]. In the fission reaction of the $^{235}$U nucleus the $^{137}$Cs isotope is produced, which is used in radiation therapy, because of its suitable half-life. $^{125}$Te (p,xn) reaction, during which the iodine isotope can be produced, was simulated in the 5.5–100.5 MeV energy range using TALYS code in [4]. The calculated $^{125}$Te (p,xn) cross sections have been compared with results obtained using ALICE/ASH code.

Aside from the medical studies, TALYS code was also used in photomolecular applications. Zirconium is a very strong metal and it is the best construction material for nuclear reactor parts, like cladding of fuel elements, due to its low neutron capture cross-section. The zirconium is also a potential target for the production of medical isotopes. For this reason, the cross sections of ($\gamma$,n) reaction in nat$^{90}$Zr, $^{90}$Zr, $^{91}$Zr, $^{92}$Zr, $^{94}$Zr and $^{96}$Zr targets have been calculated using the TALYS code in [5].

2. Materials and methods

$^{99m}$Tc, $^{111}$In and $^{57}$Co are the radioisotopes used in nuclear medicine. $^{100}$Mo, $^{58}$Fe and $^{112}$Cd isotopes are also used in medicine. $^{99m}$Tc, $^{111}$In and $^{57}$Co are used as target materials for the production of radioisotopes. These radioisotopes are used in kidney imaging.

In this study, the cross sections of $^{100}$Mo (p,2n) $^{99m}$Tc, $^{58}$Fe (p,2n) $^{57}$Co, $^{112}$Cd (p,2n) $^{111}$In reactions were calculated. The calculations were carry out using TALYS 1.6 program for Monte Carlo simulation of nuclear reactions. TALYS 1.6 [6] program examines the interaction with the nucleus, with a mass of 12 or heavier, of incoming particles like protons, neutrons, deuterons, tritons, gamma, alpha and 3He particles in the energy range of 1 keV–1 GeV. It is written in FORTRAN programming language and runs on Linux operation system.
3. Results and discussions

The calculated $^{100}$Mo (p,2n) $^{99m}$Tc, $^{58}$Fe (p,2n) $^{57}$Co, $^{112}$Cd (p,2n) $^{111}$In production reaction cross sections are shown in Figs. 1, 2 and 3.

The obtained results are compared with the experimental data existing in the EXFOR [7] databases.

4. Conclusions

In this work production cross sections for the reactions of $^{100}$Mo (p,2n) $^{99m}$Tc, $^{58}$Fe (p,2n) $^{57}$Co and $^{112}$Cd (p,2n) $^{111}$In were calculated in the energy range between 1 and 100 MeV. Our results are in fair agreement with experimental data available in literature. The maximum cross section values are 1008.45 mb at 16.5 MeV for $^{99m}$Tc production, 1021.14 mb at 20.5 MeV for $^{111}$In and 591.477 mb at 19.5 MeV for $^{57}$Co production. The most appropriate production range for Tc-99m using $^{100}$Mo (p,2n) $^{99m}$Tc nuclear reaction is 13–18 MeV. The most appropriate production range for $^{111}$In using $^{112}$Cd (p,2n) $^{111}$In nuclear reaction is 16–23 MeV. The most appropriate production range for $^{57}$Co using $^{58}$Fe (p,2n) $^{57}$Co nuclear reaction is 16–20 MeV.

Reaction cross sections for production of $^{99m}$Tc, $^{111}$In and $^{57}$Co medicine radioisotopes were calculated theoretically. The calculated results were compared with the results of experimental data from literature. It is seen that the theoretical results calculated using the TALYS 1.6 program are compatible with the experimental data taken from literature.
