Influence of Si and Co substitution for Fe in rapidly quenched $\text{Fe}_{86}\text{B}_{14}$ -type alloy (metallic ribbons form) on the crystallization temperature, crystal structure and magnetic properties are reported for three different metallic glasses: $\text{Fe}_{86}\text{B}_{14}$, $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$, and $\text{Fe}_{80}\text{Co}_4\text{Si}_2\text{B}_{14}$. At first, the onset temperatures of crystallization process were determined for both bcc-Fe (primary crystallization) and bct- Fe_3B phase types (secondary crystallization) by calorimetric measurements with use of $10^\circ\text{C}/\text{min}$ heating rate. On the basis of obtained results, the conventional heat treatment process (with heating rate $10^\circ\text{C}/\text{min}$ and subsequent isothermal annealing) for wound toroidal cores has been optimized in order to obtain best soft magnetic properties (minimum value of coercivity H_c and magnetic core loss P_s) at frequency $f = 50$ Hz. For the optimal annealed samples the complex magnetic permeability (μ' , μ'') was measured, in the frequency range 10^4 – 10^8 Hz. Finally, the stage of the crystallization process was identified by the use of X-ray diffraction (XRD) method and the transmission electron microscopy (TEM) observations.

PACS/topics: soft magnetic materials, metallic glass, magnetic properties

1. Introduction

In the last few years, new generation of high saturation induction ($B_s > 1.75$ T) nanocrystalline alloy systems including FeBCu [1], FeSiBCu [2], FeSiBPCu [3], and FeSiBPCCu [4] were successfully developed. The maximum values of B_s were obtained for Cu containing alloys, in which nanocrystallization process was governed by conventional heating with rate 10 – $40^\circ\text{C}/\text{min}$, and subsequent isothermal annealing. In 2018, Suzuki et al. [5] showed that for Cu-free binary $\text{Fe}_{86}\text{B}_{14}$ alloy the ultra-rapid annealing process (heating rate $> 100^\circ\text{C}/\text{s}$) is sufficient to obtain $B_s \simeq 1.9$ – 1.92 T, as well as relatively low $H_c \simeq 4.6$ – 6.7 A/m. According to T. Liu et al. [4], for the conventional annealing the appropriate addition of Cu allows to synchronize the crystallization, which is essential for excellent magnetic properties. Authors have demonstrated that during annealing process the microstructure goes through three stages: stress relief, nanocrystallization, and second phase precipitation. It has been also shown, that for the Cu-free alloy the difficult nucleation process leads to insufficient nucleation sites resulting in excessive grain growth [6]. The optimal magnetic properties were obtained by the annealing in the pre-nanocrystallization — stress relief stage during the relaxation process [7].

The effect of substitution of +2 at.% of Si for Fe, and further of +4 at.% of Co for Fe, in the initially Cu-free $\text{Fe}_{86}\text{B}_{14}$ binary alloy has been shown in the present work, based on magnetic properties: $B(H)$ relationship, P_s , and (μ' , μ''). The conventional heat treatment process of $\text{Fe}_{86}\text{B}_{14}$, $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$, and $\text{Fe}_{80}\text{Co}_4\text{Si}_2\text{B}_{14}$ alloys was successfully optimized. Then, the crystal structure of the annealed samples was verified by X-ray diffraction method and transmission electron microscopy observations. The results will be used to optimize newly developed ultra-rapid annealing process.

2. Experimental

The amorphous alloys with nominal compositions $\text{Fe}_{86}\text{B}_{14}$, $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$, and $\text{Fe}_{80}\text{Co}_4\text{Si}_2\text{B}_{14}$, in the form of ribbons with a 33 – 35 μm thickness and 6.5 mm width were obtained by melt spinning technique (at 30 m/s Cu wheel speed). To achieve the optimal magnetic parameters (min. value of H_c and P_s at 50 Hz, and B_s), the toroidal cores were isothermally annealed for 20 min in vacuum furnace (5×10^{-4} mbar) at different temperatures from 300°C to 420°C . Amorphousness of the as-spun and annealed ribbons were studied by X-ray diffraction (XRD) at room temperature using a Rigaku MiniFlex 600 diffractometer (CuK_α radiation). The crystallization processes have been monitored by the differential scanning calorimetry (DSC) with a heating rate of $10^\circ\text{C}/\text{min}$ using thermal analyzer Netzsch STA 449F3. Transmission electron microscopy (TEM) images in the bright-field (BF) mode, and selected area diffraction patterns (SADPs) were recorded using Tecnai G2 F20 (200 kV) electron microscope. C-1200 (MAGNET-PHYSIK Dr. Steingroever GmbH) magnetic measurement system was used to determine $B(H)$ and P_s . The complex magnetic permeability in the frequency range 10^4 – 10^8 Hz at room temperature of the toroidal cores was measured using impedance analyzer Agilent 4294A.

3. Results and discussion

The fully amorphous state was verified by XRD, and no evidence of surface crystallization has been found. The DSC curves are shown in Fig. 1. Two exothermal crystallization peaks are visible in the presented thermograms. The first peak (at T_{x1}) corresponds to the α -Fe crystallization process (bcc-Fe type structure), while the second (at T_{x2}) to the bct-Fe₃B type phase crystallization process. The calculated difference between the onset temperatures of two peaks $\Delta T = T_{x2} - T_{x1}$ is equal to $\sim 103^\circ\text{C}$ for Fe₈₆B₁₄, $\sim 83^\circ\text{C}$ for Fe₈₄Si₂B₁₄, and $\sim 99^\circ\text{C}$ for Fe₈₀Co₄Si₂B₁₄ alloy. The shift of both T_{x1} and T_{x2} to the higher values for alloys with higher silicon content indicates the increase of the thermal stabilities of the amorphous alloys against crystallization, and is consistent with the previous observations [8]. The cobalt substitution for iron decreases value of T_{x1} from 414°C to 402°C , in turn slightly increases value of T_{x2} onset temperature from 497°C to 501°C . This effect of Co substitution is well known in the literature [7].

By investigating the effect of annealing temperature on magnetic properties it was possible to determine optimum annealing temperature. The desirable minimal values of H_c and P_s were obtained for the following annealing temperatures T_a : 320°C for Fe₈₆B₁₄, 330°C for Fe₈₄Si₂B₁₄, and 330°C for Fe₈₀Co₄Si₂B₁₄. The measured hysteresis loops are presented in Fig. 2. The magnetic parameters such as: B_s , H_c , remanence B_r , calculated P_s values, and squareness factor $S_f = B_r/B_s \times 100\%$ have been gathered in Table I. The optimized T_a values are much smaller than T_{x1} . The difference between T_{x1}

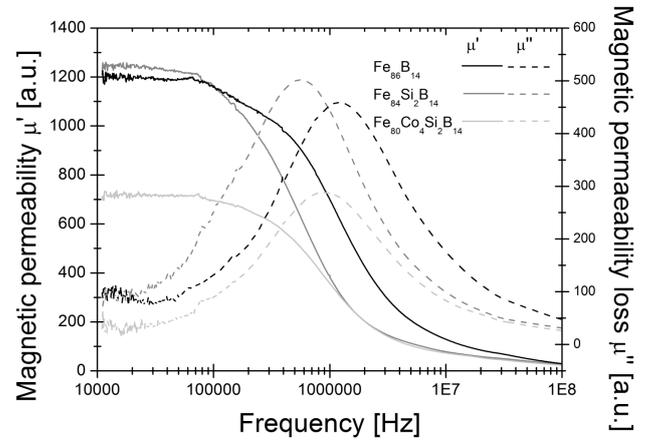

Fig. 3. 3: Magnetic permeability μ' and magnetic permeability loss μ'' dependence in the function of frequency 10^4 – 10^8 Hz for annealed samples.

TABLE I

Magnetic parameters: magnetic saturation B_s , coercivity H_c , remanence B_r , core losses P_s , and squareness factor $S_f = (B_r/B_s) \cdot 100\%$.

Sample	B_s [T]	B_r [T]	H_c [A/m]	P_s [W/kg]	S_f [%]
Fe ₈₆ B ₁₄	1.52	0.724	12.6	0.68	47.6
Fe ₈₄ Si ₂ B ₁₄	1.62	0.878	10.8	0.53	54.2
Fe ₈₀ Co ₄ Si ₂ B ₁₄	1.69	0.61	23.6	1.8	36.1

and T_a , defined as $T_d = T_{x1} - T_a$, equals 45°C , 84°C , and 72°C , for Fe₈₆B₁₄, Fe₈₄Si₂B₁₄, and Fe₈₀Co₄Si₂B₁₄, respectively. As it was shown in [4] for Cu-free alloys there is only one optimal annealing temperature that should be found at the early stage of nanocrystallization process, just after so called “stress relief” stage.

In case of Fe₈₆B₁₄ the H_c value of reaches 12.6 A/m, and $P_s = 0.68$ W/kg. The value of B_s at 3000 A/m is 1.52 T, while $B_r = 0.724$. Thus, the calculated

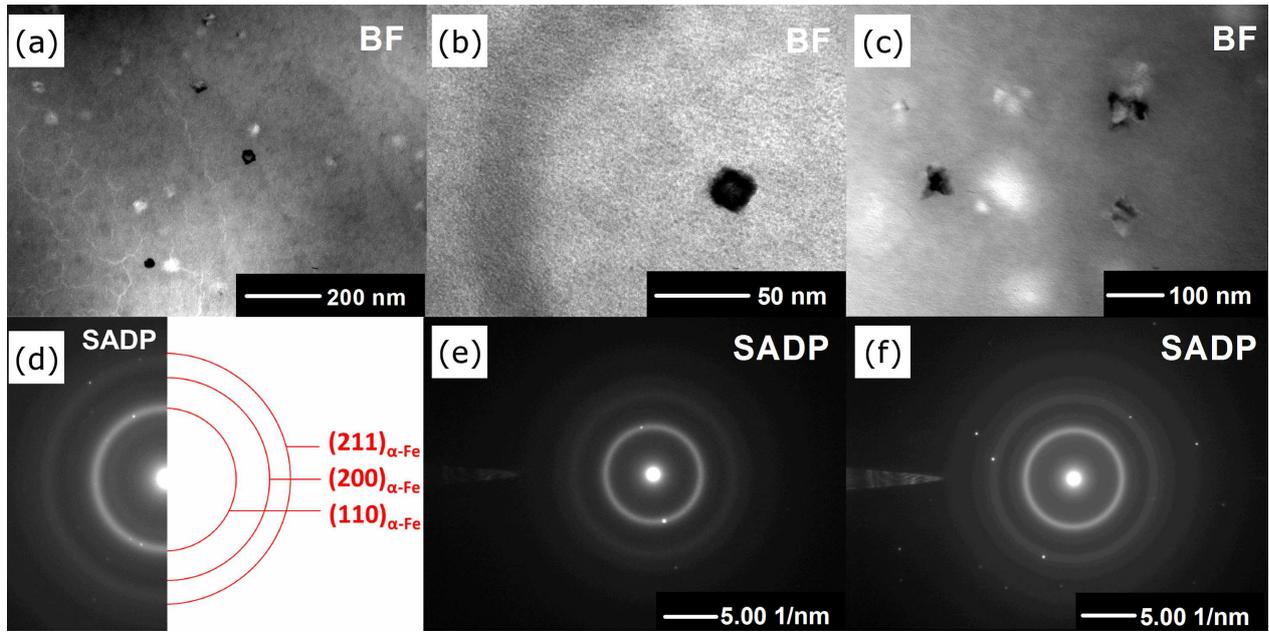

Fig. 4. TEM images of annealed samples: (a) BF of $\text{Fe}_{86}\text{B}_{14}$, (b) BF of $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$, (c) BF of $\text{Fe}_{80}\text{Co}_4\text{Si}_2\text{B}_{14}$, (d) SADP of $\text{Fe}_{86}\text{B}_{14}$, (e) SADP of $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$, (f) SADP of $\text{Fe}_{80}\text{Co}_4\text{Si}_2\text{B}_{14}$.

S_f is 47.6%. In case of $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$ alloy H_c decreases to 10.8 A/m, P_s decreases to 0.53 W/kg, while B_s increases up to 1.62 T, as well as S_f to 54.2%. Similar effect of soft magnetic enhancement by limited addition of Si was observed by Ohta et al. [9]. For Co containing sample, the B_s value increases up to 1.69 T at 3000 A/m, while unfortunately H_c and P_s also increase to 23.6 A/m and 1.8 W/kg, respectively. Together with deterioration of soft magnetic properties S_f decreases to 36.1%.

The frequency dependent μ' and μ'' permeabilities are gathered in Fig. 3. For binary Fe-B alloy μ' reaches 1200 for $f = 10^4$ – 10^5 Hz, and the maximum value of losses μ'' is observed at 10^6 Hz. The soft magnetic properties of Si substituted alloy are slightly enhanced. The value of μ' has been increased to 1270 with maximum value of μ'' shifted to 5×10^5 Hz, which may suggest that the size of nanocrystals has been slightly increased compared to Fe-B alloy. For Co containing alloy, deterioration of soft properties is visible through the decrease of μ' to the value $\mu' = 700$. The maximum of μ'' is observed at $f = 9 \times 10^5$ Hz.

The first crystal structure verification of the annealed samples have been done by XRD method, and there were only very weak peaks emerging in the position of the α -Fe phase. In fact, TEM observations in BF mode (Fig. 4a–c) and SADPs (Fig. 4d–f) for all samples proved the presence of α -Fe nanocrystals of ~ 25 nm in all samples. However the number of nanocrystals was very limited, and decreasing for single nanocrystals for $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$ alloy, while increasing number of nanocrystals for Co containing alloy. Basing on TEM observations the stress relief/pre-nanocrystallization stage for all samples is visible. Low and high density amorphous states coexist

with few number of nanocrystals, and such local atomic arrangement might be responsible for good magnetic properties.

4. Conclusion

The structural and magnetic properties of conventionally annealed $\text{Fe}_{86}\text{B}_{14}$, $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$ and $\text{Fe}_{80}\text{Co}_4\text{Si}_2\text{B}_{14}$ alloys prepared by melt spinning have been investigated. The main conclusions are as follows:

The optimum T_a values are much smaller than T_{x1} . The difference $T_{x1} - T_a$ is equal to: 45 °C for $\text{Fe}_{86}\text{B}_{14}$, 84 °C for $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$, and 72 °C for $\text{Fe}_{80}\text{Co}_4\text{Si}_2\text{B}_{14}$. TEM BF images for annealed samples prove the existence of early stage of nanocrystallization process with limited numbers of α -Fe nanocrystals ~ 25 nm. For $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$ alloy the amorphous state is the most stable, and only single nanocrystals occur.

Annealed $\text{Fe}_{84}\text{Si}_2\text{B}_{14}$ alloy with the smallest nanocrystals content exhibits the best soft magnetic properties with $B_s = 1.62$ T, $H_c = 10.8$ A/m, $P_s = 0.53$ W/kg, and highest $\mu' = 1200$ in the range of 10^4 – 10^5 Hz with maximum value of μ'' at $f = 10^6$ Hz.

The Co addition increases B_s up to 1.69 T, while deteriorates the soft magnetic properties: $H_c = 23.6$ A/m, $P_s = 1.8$ W/kg, and μ' of ~ 700 .
